8

9 An environmental reconstruction based on palynological evidence preserved in peat was
10 carried out to examine late Holocene alpine tree line dynamics in the context of past climatic
11 changes on Galdhøpiggen (Jotunheimen, southern Norway). We analysed a peat core taken
12 from a mire at the present-day tree line (1000 m a.s.l.), c. 450 m downslope from the lower
13 limit of sporadic permafrost. We adopted a combination of commonly used indicators of
14 species' local presence to reconstruct past vegetation assemblages, such as the relative pollen
15 abundance (%), pollen accumulation rate (PAR), and presence of indicator species.
16 Additionally, fossil pollen from the peat sequence was compared to modern pollen from a
17 surface moss polster in order to establish a modern analogue. The results were compared with
18 studies covering the late-Holocene climatic changes in the area. The reconstruction
19 demonstrates that a pine-dominated woodland reached above the present-day tree line at c.
20 4300 cal. yr BP, suggesting a warmer climate suitable for Scots pine (*Pinus sylvestris*) growth
21 at this altitude. Scots pine retreated to lower altitudes between c. 3400-1700 cal. yr BP,
22 accompanied by the descent of the low-alpine shrub-dominated belt, in response to cooling
23 climatic conditions. The colder period covered c. 1700–170 cal. yr BP, and an open downy
24 birch (*Betula pubescens*) woodland became widespread at 1000 m a.s.l., whilst pine remained
25 sparse at this altitude. From c. 170 cal. yr BP onwards, warming allowed pine to re-establish
26 its local presence alongside downy birch at 1000 m a.s.l.

28 **Introduction**

29 Over the past decades, northern mountainous areas have been experiencing the thawing of
30 permafrost and alterations in vegetation patterns in response to increasing temperatures. Such

31 changes have been recorded on Galdhøpiggen (Jotunheimen, Norway), the highest mountain
32 in northern Europe and the subject of the current study. Previous studies carried out on
33 Galdhøpiggen have recorded the decadal-scale warming of near-surface permafrost (Isaksen et
34 al., 2007) and mean ground temperatures (Isaksen et al., 2011). Models indicate that the lower
35 limit of permafrost has moved upslope by 200 m since 1860, to its present-day altitude of
36 c.1450 m a.s.l. (Hipp et al., 2012). Concurrently, aerial photographs reveal upward altitudinal
37 shifts in vegetation (notably *Betula pubescens*) on the north-facing slope over recent decades
38 (Hallang et al., 2020). At higher elevations, shrub encroachment on Galdhøpiggen has been
39 found to have a larger control over surface CO₂ emissions than geomorphological factors
40 (Hallang et al., 2020).

41 To understand the response of northern alpine vegetation communities and tree lines to
42 changing air temperatures, it is necessary to examine the patterns of such vegetation shifts over
43 longer time periods. Past alpine tree line movements can assist in identifying warmer and colder
44 periods, and allow inferences about permafrost degradation and aggradation. In turn,
45 examining the long-term vegetation- and permafrost dynamics could contribute to improving
46 our understanding of the role of northern alpine regions in the future carbon cycle. Here, we
47 analyse a palaeoecological sequence in order to gain insight into centennial- and millennial-
48 scale movements of vegetation communities on the slope of Galdhøpiggen in response to past
49 climatic changes.

50 Alpine regions are particularly suitable for studying vegetation dynamics, as they are sensitive
51 to climatic variations and provide a setting where climatic and environmental conditions vary
52 over short distances. Past palynological studies have used tree lines at their altitudinal limits as
53 proxies to infer past climatic conditions in Norway (Aas, 1969; Barnett et al., 2001; Bjune,
54 2005; Caseldine, 1984; Eide et al., 2006). Here, we define the tree line as a general boundary
55 area connecting the highest altitudinal patches of woodland on the north-facing slope of
56 Galdhøpiggen (Aas, 1969; Körner, 1999). As the position of alpine tree lines is mainly
57 controlled by temperature, they can be highly sensitive to even a small change in climate
58 (Caseldine, 1984; Eide et al., 2006; Kullman, 2002). For example, tree lines in the Scandes
59 have advanced by hundreds of metres in response to warming since 1950 (Kullmann, 2002).
60 Therefore, a record of tree line trends over several thousand years can provide insight to past
61 climatic changes.

62 The historic altitudinal movements of vegetation belts can be reconstructed from sedimentary
63 deposits (peat- and lake deposits), whilst modern pollen trapped in moss polsters can be used
64 to calibrate the palaeoecological record. However, an accurate estimation of the past vegetation
65 composition based solely on palynological data is not as straightforward as simple
66 quantification of pollen abundance, due to the differences in pollen production and dispersal
67 methods between species. Here, we adopt a combination of commonly used indicators of local
68 species' presence to reconstruct past vegetation assemblages on the slope of Galdhøpiggen. A
69 peat core with an accompanying surface moss polster was taken from a mire near the present-
70 day tree line at 1000 m a.s.l., 450 m downslope of the present-day lower limit of permafrost.
71 Fossil- and modern pollen were extracted from the peat and moss polster and identified. The
72 interpretation of data is enhanced by combining several approaches: (1) relative pollen
73 abundance (%) is compared with thresholds from the literature; and (2) modern pollen
74 abundance is compared with fossil assemblages. Pollen accumulation rates (PAR) and indicator
75 species provide additional insight to past vegetation composition.

76 Galdhøpiggen has been the focus of several permafrost- and vegetation studies, which provide
77 comprehensive background condition data over recent decades. Holocene climatic history and
78 variability in the Jotunheimen region have also been extensively studied. Periods of glacial
79 expansions and retreats since the beginning of the Holocene have been inferred from
80 glaciolacustrine sediment cores (e.g. Matthews et al., 2000) and from minerogenic sediment
81 layers in stream-bank mires (e.g. Matthews and Dresser, 2008). Holocene ground temperatures
82 and permafrost extents on Galdhøpiggen have previously been modelled using temperature-
83 monitored boreholes for model calibration (Hipp et al., 2012; Lilleøren et al., 2012).
84 Combining the existing climate reconstructions with local palynological data will contribute to
85 improving the interpretation of changing environmental conditions on Galdhøpiggen over the
86 past ~4400 years.

87 The specific objectives of this study are: (i) to reconstruct the late-Holocene vegetation
88 assemblages on Galdhøpiggen and describe their patterns of distribution through time; and (ii)
89 to analyse the reconstructed vegetation dynamics to infer the late-Holocene climatic conditions
90 and permafrost limits on Galdhøpiggen.

91

92 **Methodology**

93 *Study site*

94 A 46 cm *Sphagnum* peat core was collected from a small mire (Figure 1) situated at 1000 m
95 a.s.l. on the north-facing slope of Galdhøpiggen mountain in NE Jotunheimen, Norway
96 (61°43'07.4"N, 8°23'58.7"E), approximately 250 m southeast of Raudbergstultjønne Lake.
97 The mire is c. 460 m below the lower limit of discontinuous permafrost, which was most
98 recently estimated at around 1450-1470 m a.s.l. (Farbrot et al., 2011; Isaksen et al., 2011).

99 The coring site lies approximately on the present-day tree line (Figure 1), near the upper
100 boundary of the sub-alpine vegetation belt (Table 1). The upper altitudinal limit of the mixed
101 pine-birch woodland at 1050 m a.s.l. (Figure 1) represents the 'timber line', or the limit of the
102 continuous forest in the area. This is also the altitudinal limit of *Pinus sylvestris* (Scots pine),
103 both here and in Jotunheimen (Bjune, 2005). The tree line extends up to almost 1200 m a.s.l.,
104 and consists of stands of *Betula pubescens* (downy birch). Tree line positions have been related
105 to the temperatures of the warmest month in the area (Körner, 1999) or a minimum of 100 days
106 per year over 5°C (Ellenberg, 1963). Paus (2010) estimated that *Pinus sylvestris* requires
107 minimum July mean temperatures of c. 11°C for growth in central Norway, whilst Nesje and
108 Kvamme (1991) found that mean June-September temperatures of at least 7°C are required for
109 *Betula pubescens*.

110 Based on data from the Fokstua meteorological station (60 km from site), the 2010-2019 mean
111 July air temperature at c. 1000 m a.s.l. in the area is 11.4°C and the mean growing season (June-
112 September) temperature is 9°C (NOAA, 2020). The mean number of days above 5°C per year
113 was 121 during the past decade, a considerable increase from an annual mean of 110 days
114 during 1950s, 1960s and 1970s (NOAA, 2020).

115

116

[Insert Figure 1 here]

117

118 The strategic location of the mire was selected to obtain a core with a surface moss polster that
119 would contain a pollen assemblage representative of the vegetation at the present-day tree line.
120 The surface vegetation on the mire is dominated by *Sphagnum* moss and sedges (e.g.
121 *Eriophorum* spp.), with scattered shrubs including *Betula nana* (dwarf birch) and *Salix*
122 (willow) species (*S. herbacea*, *S. glauca*). The mire is surrounded by a sparse stand of *Pinus*
123 *syvestris* c. 260 m to the north, mixed with individual junipers (*Juniperus communis*).
124 Approximately 200 m to the south, scattered stands of *Betula pubescens* are mixed with *Salix*

125 spp. and *Betula nana*. A birch-dominated mixed woodland is found 500 m to the east of the
126 coring site, whilst the mixed woodland 600 m to the west is dominated by pine. The vegetation
127 belts on Galdhøpiggen are described in Table 1.

154

155

156 *Sample collection*

157 A 50 cm Russian peat corer with a 5 cm chamber diameter was used to collect a 46 cm-long
 158 core (including a 5 cm moss polster) from the centre of the mire. Whilst the peat layer extended
 159 deeper, only the top 46 cm was extracted and analysed for the purposes of this study. The core
 160 was wrapped in plastic film and placed in a plastic tube for transportation. Prior to sub-

161 sampling, the core was stored in dark conditions at 5°C. For laboratory analyses, the core was
162 sub-sampled at one centimetre resolution to produce a total of 46 samples. A modified syringe
163 was used to measure out a known volume (1 cm³) of peat material per sample. Based on
164 previous studies that estimated the pollen deposition time in moss polsters in Scandinavia
165 (Lisitsyna and Hicks, 2014; Pardoe et al., 2010; Von Stedingk et al., 2008), the 5-cm *Sphagnum*
166 moss polster covering the peat was assumed to represent c. four years of pollen accumulation.
167 To examine the pollen composition throughout the moss, the polster was cut into segments at
168 1 cm resolution from the top down. To ensure that enough pollen was extracted from each
169 segment, 2 cm³ of material was measured out for analysis.

170 To determine the organic matter content and density of the peat, loss-on-ignition analysis was
171 undertaken following the method outlined by Chambers et al. (2011). The core was sub-
172 sampled at 2 cm intervals (covering depths between 16-44 cm due to the lack of sediment in
173 the top 6-15 cm). Samples with known volume (1 cm³) were dried overnight at 105°C in
174 weighed crucibles to determine the dry weight of each sample. The samples were then ignited
175 at 550°C for four hours to combust all organic matter, cooled to room temperature in a
176 dessicator and weighed again.

177

178 *Pollen extraction*

179 Pollen extraction followed the standard method by Bennett and Willis (2001). Two
180 *Lycopodium* spore tablets (Batch no. 3862) with known concentration of spores were used per
181 sample as a marker to calculate the concentration of pollen (Stockmarr, 1971). The samples
182 were first treated with hot HCl, humic acids were broken down with hot NaOH and sieving
183 through a 180 µm sieve removed large particles from the peat material. Initial samples were
184 tested with and without the use of hydrofluoric acid (HF). Due to the high organic matter
185 content of the samples, the use of HF was determined to be unnecessary after the trial. All
186 samples were subjected to three minutes of acetolysis to remove polysaccharides. To increase
187 the contrast of pollen grains, 0.2% aqueous safranin was added to stain the pollen. The samples
188 were mounted on glass slides using silicone oil.

189

190 *Pollen counting*

191 A Leica (DM 2000) light microscope was used at x400 and x1000 magnification to identify
192 and count the pollen. A minimum of 500 total land pollen (TLP) were counted at each depth;
193 the sum includes all pollen taxa and spores (*Sphagnum* and Filicales). Moore (1994), Reille
194 (1992) and a collection of reference slides held in the Department of Biosciences, Swansea
195 University, were used to identify the pollen grains and the spores. Due to their different growth
196 forms and ecological significance, pollen belonging to the genus *Betula* was identified to
197 species level where possible as either *Betula nana*, *Betula pubescens* (Birks, 1968) or *Betula*
198 hybrid (Karlsdóttir et al., 2008). The division was based on visual assessment of pollen
199 combined with measurements of diameter (mean values: *B. nana* = 20.42 μm , *B. pubescens* =
200 24.20 μm) and pore depth (mean values: *B. nana* = 2.20 μm , *B. pubescens* = 2.81 μm) of
201 individual grains. A number of *Betula* pollen grains that were damaged or deformed and
202 therefore difficult to identify were counted as *Betula undiff.*

203

204 *Radiocarbon dating and age calibrations*

205 The humin fraction of three peat samples (taken at 10 cm, 24 cm and 46 cm depth) was dated
206 using accelerator mass spectrometry (AMS) radiocarbon dating. The resulting ^{14}C dates for
207 samples taken at depths of 24 cm and 46 cm were converted to calendar ages (cal. yr BP =
208 calendar years before present [1950]) using the calibration software CALIB (8.2) (Stuiver et
209 al., 2021) and the northern hemisphere terrestrial calibration curve IntCal20 (Reimer et al.,
210 2020). The dates were determined using 2σ error (Stuiver and Reimer, 1993) meaning that
211 there is a 95% probability that the reported median calibrated age falls within the estimated age
212 range. The ‘greater than modern’ (F^{14}C) radiocarbon date at 10 cm depth was calibrated using
213 the post-bomb northern hemisphere calibration dataset ‘NHZ1’ by Hua et al. (2013), and the
214 online calibration resource CALIBomb (available from: calib.org/CALIBomb/).

215

216 *Pollen diagrams*

217 Pollen relative abundance (%) and concentration ($\text{grains}/\text{cm}^3$) were calculated following
218 Bennett and Willis (2001). All pollen diagrams were created using psimpoll (4.27) (Bennett,
219 2000). Statistically significant pollen assemblage zones based on the relative pollen abundance
220 diagram were determined using binary splitting by sums-of-squares and constrained cluster
221 analysis (CONISS); both methods resulted in the same output (Grimm, 1987). The influx

222 diagram illustrating the pollen accumulation rates (grains cm⁻² year⁻¹) for nine dominant taxa
223 was created using input files with concentration values and calibrated ages for dated depths.
224 PARs were not calculated for the modern moss polster because the exact age-span of the polster
225 is not known.

226

227 *Methods of analysis*

228 Detection of Holocene tree line positions and dynamics based on pollen relative abundance is
229 difficult (Aario, 1940; Birks and Bjune, 2010; Seppä and Hicks, 2006). Firstly, estimating the
230 local presence of species through traditional pollen analysis is complicated because the
231 relationships between pollen deposition and vegetation cover are rarely straightforward.
232 Differences in the pollen type, production and dispersal methods of individual plant species,
233 but also atmospheric conditions (e.g. wind speed and dominant direction) and topography will
234 play a role in how and where pollen is deposited for long-term preservation (Jackson and
235 Lyford, 1999). Secondly, *B. pubescens* and *P. sylvestris* have been found to produce less pollen
236 near their altitudinal limits than at lower altitudes in Norway (Eide et al., 2006). Above the tree
237 line, pollen production by local tundra species is similarly low, and pollen records are often
238 dominated by long-distance derived tree pollen (up to 90%), masking the local tundra pollen
239 component (Birks and Bjune, 2010; Pardoe, 2006; 2014).

240 Being aware of the complications regarding the use of pollen data to delineate past tree lines,
241 and acknowledging the limitation posed by the absence of macrofossil analysis (Birks and
242 Birks, 2000), we do not attempt to determine the exact position of the tree lines at any given
243 time. Instead, we aim to describe the directions of past trends in vegetation cover, and draw
244 general conclusions about the late Holocene environmental conditions on Galdhøpiggen in the
245 context of previous publications. To achieve this, we combine several proxies (relative pollen
246 abundance, PAR, and indicator species) to interpret the pollen data. Relative pollen abundance
247 has been used as an indicator of the presence of local taxa (e.g. Barnett et al., 2001; Huntley
248 and Birks, 1983; Lisitsyna et al., 2011), and pollen percentage threshold values have been
249 estimated for dominant European tree species to differentiate between local and regional pollen
250 (compiled in Table 2). However, the use of relative pollen abundance alone to reconstruct past
251 assemblages in open alpine tundra environments can be misleading, as it cannot distinguish
252 between local and regional pollen (Birks and Bjune, 2010; Prentice and Webb, 1986). For
253 example, Barnett et al. (2001) reported periods of local presence of birch and pine throughout

254 the Holocene in Leirdalen, Norway (approximately 14 km from our site, at 920 m a.s.l.) based
255 on relative pollen abundance (>10% and 55%, respectively). Conversely, similar relative
256 abundance values of arboreal pollen (15-35% of birch, 20-60% of pine) were recorded in
257 surface moss polsters collected from modern open pioneer communities on a nearby glacial
258 foreland at Storbreen, far from tree cover (Pardoe, 2006).

259 Similarly, we have used the relative abundance of modern pollen in the surface moss polster
260 (and in the top five centimetres of peat in our core) to establish a modern analogue and allow
261 for comparison with fossil pollen assemblages in the peat. This tested approach allows a direct
262 linkage of present-day pollen and vegetation, which can then be used to make inferences about
263 palaeo-relationships (e.g. Caseldine, 1989; Caseldine and Pardoe, 1994; Jackson, 1991; Pardoe,
264 1996, 2006, 2014). Surface moss polsters are estimated to represent two to five years of pollen
265 deposition and are considered a good analogue for determining plant community composition
266 within palaeoecological records, but they cannot be used to calculate PAR if the exact age of
267 the moss polster is unknown (Lisitsyna and Hicks, 2014; Pardoe, 2006). Moss polsters are
268 useful for estimating local vegetation composition in tundra environments, where the relevant
269 source area of pollen is relatively small (600-800 m) (Oswald et al., 2003).

270 To further characterise the Galdhøppigen palaeo-vegetation, we examined pollen accumulation
271 rates throughout the core. PARs represent the net number of grains accumulated per unit area
272 of sediment surface per unit time (Davis, 1969). PARs are not affected by the presence or
273 absence of other (abundant) taxa in the pollen profile, allowing each taxon to be analysed
274 individually over space and through time. Assessment of PARs have been used to determine
275 species' local presence (Kuoppamaa et al., 2009) and to quantify the presence of birch, pine
276 and spruce at their latitudinal limit in northern Fennoscandia (Hicks, 2001). Using a network
277 of pollen traps to estimate deposition rates over 18 years, Hicks (2001) found that the long-
278 term average pollen deposition is an accurate indicator of the local presence, absence and
279 abundance of arboreal species. The PAR threshold values for pine and birch presence from
280 Hicks (2001) are also outlined in Table 2.

281

282

283

284

285 **Table 2.** Threshold values of *Betula pubescens*, *Pinus sylvestris* and *Picea abies* pollen accumulation
 286 rates (grains cm⁻² yr⁻¹) and relative pollen abundance (%) from the literature indicating local and
 287 regional presence of arboreal species.

		<i>Betula</i> <i>pubescens</i>	<i>Pinus</i> <i>sylvestris</i>	<i>Picea</i> <i>abies</i>
<i>Hicks (2001)</i>	Not present			
PAR	within 10 km	N/A	<300	<25
(grains cm ⁻² yr ⁻¹)				
	Not present			
	within 1 km	<500	300-500	25-50
	Sparse presence	500-1000	500-1500	50-100
	Open forest	1000-1500	1500-2000	100-300
	Dense forest	>1500	>2000	>300
<i>Huntley and</i>	Local presence	10%	>25%	5%
<i>Birks (1983)</i>

	Dominant woodland	50%	N/A	N/A
<i>Lisitsyna et al.</i>	Regional presence	5%	10%	1-5%
(2011)				
% values				

288

289 Finally, we have identified several species in our pollen profile that may be indicative of certain
 290 environmental conditions. This approach has been evaluated in more detail by Birks et al.
 291 (2010), and introduced in more detail in the discussion.

292 **Results**

293 The peat is relatively uniform and consists of well-humified organic matter. The organic matter
 294 content is high (87-91%) throughout the tested 41 cm of peat material. The bulk density of the
 295 samples ranges from 0.14 to 0.23 g cm⁻³, showing a gradual decline with increasing depth. The
 296 ash-free bulk density (organic matter density) shows a similar decline, from 20 to 12 g cm⁻³.

297 The radiocarbon dates for three depths (10, 24 and 46 cm) and calibrated ages are listed in
298 Table 3.

299

300 **Table 3.** Radiocarbon dates and age calibrations using the IntCal20 calibration curve (Reimer et al.,
301 2020) and the post-bomb calibration dataset ‘NHZ1’ (Hua et al., 2013).

302	Depth (cm)	Laboratory ref. code	¹⁴ C Age (years BP)	F ¹⁴ C	Calibrated Age
303	10	UBA-44553	-	1.0915± 0.0021	2000 ± 1 AD
304					
305	24	UBA-42480	2872 ± 24	-	2997 ± 76 cal. yr BP
306	46	UBA-42479	3918 ± 32	-	4332 ± 91 cal. yr BP
307					

308

309 An age-depth model (Figure 2) based on linear interpolation between the three dated levels of
310 the core (10, 24 and 46 cm) and the surface was created using the ‘clam’ (2.2) package (Blaauw,
311 2010) in R (3.6.3) (R Core Team, 2021). The input file contained both ¹⁴C ages and the
312 calibrated F¹⁴C date. By default, ‘clam’ uses the IntCal13 calibration curve from Reimer et al.
313 (2013) for ¹⁴C ages. To include the F¹⁴C date, we selected the post-bomb calibration curve
314 ‘NHZ1’ by Hua et al. (2013). The non-¹⁴C dates (i.e. at 10 cm and at the surface) were assigned
315 negative values to indicate their departure from 1950 AD to present. For example, the
316 calibrated date at 10 cm is c. 2000 AD, therefore this depth was assigned the value ‘-50’ in the
317 input file. The surface of the consolidated peat core is set at 6 cm, excluding the modern moss
318 polster. Assuming that the 5 cm thick moss polster represents two to four years of accumulation
319 (Lisitsyna and Hicks, 2014) and the core was collected in 2018, the age of the surface was set
320 to 2014 (represented by ‘-64’ in the input file).

321

322 **[Insert Figure 2 here]**

323

324

325 Accumulation rates vary throughout the core. Between 46 and 24 cm, accumulation rates are
326 relatively high, and 1 cm of peat covers 61 years. The rates drop between 24 and 10 cm, where
327 1cm covers 217 years. The remaining 4-cm section of peat at the top corresponds to only three
328 years of accumulation per 1 cm. This apparently disproportionately high rate of accumulation
329 can be explained by a combination of incomplete decomposition of the less compacted and less
330 consolidated near-surface peat. Direct comparisons between the top and deeper parts of the
331 core should be made with caution (*cf.* Young et al., 2019). In our study we therefore excluded
332 the PARs of the section of the peat core between six and nine centimetres from the influx
333 diagram (see Figure 4). However, as the top five centimetres of peat date post-2000, the relative
334 abundance of pollen from this section can be used in comparison with deeper peat layers.

335

336 *Zone 1 (4350 - 3430 cal. yr BP)*

337 The relative abundance of arboreal pollen (86-92%) is high in the basal zone of the pollen
338 profile (Figure 3). *Pinus sylvestris* pollen dominates the percentage diagram (45-64%),
339 followed by *Betula pubescens* (20-35%). Both exhibit highest PARs at c. 3670 cal. yr BP (6500
340 and 3000 grains cm⁻² year⁻¹, respectively). Other arboreal taxa, i.e. *Alnus*, *Quercus*, *Sorbus*,
341 *Ulmus*, *Juniperus* and *Tilia*, are represented by small quantities of pollen (<3%). The
342 proportions of shrub and herb pollen increase in the upper portion of the zone. The relative
343 abundance of *Empetrum nigrum* pollen increases from 0.2% to 3%, with *Betula nana* and *Salix*
344 pollen following a similar pattern. The highest relative pollen abundance of some herb genera
345 throughout the 4400-year sequence (e.g. Asteraceae, *Filipendula*, *Rumex*) are recorded in this
346 zone, whilst other genera (e.g. *Valeriana*, *Plantago*) appear exclusively in this time period. The
347 relative abundance of Filicales spores decreases from 4% to 0.8% in Zone 1, and *Sphagnum*
348 spore abundance increases from <0.5% to 1%.

349

350 *Zone 2 (3430 – 1690 cal. yr BP)*

351 A sharp decrease in PAR for all taxa is evident in the middle of Zone 2. Arboreal pollen relative
352 proportions drop to the lowest values of the entire profile (77%), before recovering to 91% by
353 1690 cal. yr BP. *Pinus sylvestris* pollen exhibits a consistently lower PAR (300-2600 grains
354 cm⁻² year⁻¹), and its relative abundance decreases from 57% to 16% by c. 3000 cal. yr BP,
355 recovering to 37% by c. 1690 cal. yr BP. The relative abundance of *Betula pubescens* pollen

356 fluctuates between 20% and 52% throughout the zone, with PAR comparable to *P. sylvestris*.
357 Shrub pollen abundance increases from 8% to 19% by mid-zone, followed by a decline to 6%
358 by the end of the period. *Betula nana* pollen reaches the highest PAR (500 grains cm⁻² year⁻¹)
359 and relative abundance (14%) in the profile. *Salix*, *Empetrum nigrum* and *Vaccinium* pollen is
360 recorded throughout the period ($\leq 4\%$ each). Herb pollen and spores are present in small
361 quantities in this zone ($\leq 4\%$ and $\leq 6\%$ respectively). *Epilobium angustifolium* pollen occurs,
362 whilst *Ulmus*, *Geranium* and *Apiaceae* pollen are not recorded in the profile after this time
363 period. The relative abundance of Filicales and *Sphagnum* spores both fluctuate between 0.4%
364 and 4%.

365

366 *Zone 3 (1690 cal. yr BP –2014 AD)*

367 PARs for all taxa remain low. Arboreal pollen continues to dominate the profile (84%-91%).
368 *Pinus sylvestris* pollen exhibits lowest overall PAR (<500 grains cm⁻² year⁻¹) and relative
369 abundance (18-33%). *Betula pubescens* pollen shows higher values (30-52%) and PARs (500-
370 1500 grains cm⁻² year⁻¹) exceed those of *P. sylvestris*. *Picea abies* pollen appears in the profile
371 from c. 800 cal. yr BP ($\leq 1\%$). Shrub pollen relative abundance shows a slight increase, but
372 remains between 6% and 11%. After an initial drop, *Betula nana* pollen exhibits a steady rise
373 (3-9%) throughout this zone. *Empetrum nigrum* pollen proportion declines from 4% to 1%
374 whilst *Salix* pollen abundance increases to 2%. Herb pollen drops below 1%, but regains values
375 of 3%. The relative abundance of spores declines from 2% to 0.6%. *Sphagnum* spores exhibit
376 the highest values (4%) whilst the proportion of Filicales spores remains consistently low (0.4-
377 2%).

378

379 *Zone 4: Modern moss polster (~2014-2018 AD)*

380 The relative abundance of arboreal pollen is slightly higher (87-92%) in the modern moss
381 polster compared to the underlying peat of Zone 3. *Pinus sylvestris* pollen abundance is also
382 higher here (34-43%), and comparable to the abundance of *Betula pubescens* pollen (36-42%).
383 *Picea abies* pollen is present throughout the moss at $\leq 1\%$. *Quercus* (0.5-2%) and *Alnus* (<0.4%)
384 pollen retain low presence, *Tilia cordata* pollen is recorded again after an absence in Zone 3.
385 Shrub pollen proportion is lower than in peat samples, and remains between 3-6%. Low relative
386 abundances are recorded for *Betula nana* pollen (2-5%), *Empetrum nigrum* pollen (<1%) and

387 *Salix* pollen (0.2-2%). Herb pollen abundance remains between 2-4%. Poaceae (1-2%) and
388 Cyperaceae ($\leq 2\%$) relative pollen proportions are higher than in underlying peat samples.
389 Asteraceae, *Filipendula*, *Rumex* and Ranunculaceae pollen are present, and Caryophyllaceae
390 is recorded again after being absent in Zone 3. Spores account for 0.5-3% of TLP. *Sphagnum*
391 spores exhibit a lower relative abundance in the moss polster (0-1%), whereas the proportion
392 of Filicales spores is slightly higher than in Zone 3 (up to 2%).

393

394 [insert Figure 3 here]

395 [Insert Figure 4 here]

396

397 Discussion

398 *Comparison of present-day vegetation composition with pollen from moss polster and modern*
399 *peat (2000-2018 AD)* The relative abundance of *Betula pubescens* pollen in the modern (post-
400 2000 AD) peat- and moss samples indicates the local dominance of the species (Table 2). *B.*
401 *pubescens* is undoubtedly a dominant presence in the landscape today, and forms a belt between
402 the mixed forest and the tundra, c. 200 m upslope from the coring site (Figure 1). There is a
403 slight increase in *B. pubescens* pollen abundance between 2000-2014, which could be
404 indicative of the increased abundance or maturation of the species in the area. The rapid
405 warming over the past decades has increased the mean summer temperatures at the tree line by
406 2°C, and lengthened the growing season by 11 days compared to 1950s-1970s (NOAA, 2020;
407 see Study site). Birch is highly sensitive to temperature fluctuations, because the species grows
408 quickly, reaches maturity early and has a short life span (Aas, 1969). The upslope advancement
409 of *B. pubescens* in response to warming over the past decades has previously been recorded
410 from aerial photographs in the area (Hallang et al., 2020). Whilst the climatic conditions today
411 are favourable for tree growth at even higher altitudes above the tree line, the rapidity of the
412 change has likely resulted in a lag in migratory response, as current species' compositions are
413 often determined by the climate of previous decades (Klanderud and Birks, 2003).
414 Additionally, the response is dependent on the availability of suitable substrate and habitat at
415 higher altitudes for seedling recruitment.

416 The modern pollen abundance of *Pinus sylvestris* also accurately reflects local presence. *P.*
417 *sylvestris* is less abundant around the mire compared to *B. pubescens*; the closest pine stand

418 north of the mire is sparse, and the nearest dense woodland is c. 500 m downslope (Figure 1).
419 There is also evidence of long-distance transported modern tree pollen of *Alnus*, *Quercus* and
420 *Tilia cordata*, which likely originates from further down the valley, as they are not currently
421 found near the sampling site. Whilst the presence of tree species is accurately estimated from
422 the modern samples based on the threshold values in Table 2, the non-arboreal component of
423 the surface moss sample contains some discrepancies. Despite the comparable presence of both
424 *Betula nana* and *Salix* spp. on the surface of the mire around the coring site, *Salix* is under-
425 represented in the moss sample with a mean of 0.5% in the moss (compared to 1.2% in the
426 modern peat) whilst *B. nana* accounts for 3% and 6%, respectively. A similar under-
427 representation of *Salix* pollen in 4 cm thick moss samples compared to adjacent pollen traps
428 was observed in Lisitsyna and Hicks (2014).

429 The low presence of *Salix* pollen is unexpected, especially since for mire samples, the non-
430 arboreal component of a pollen profile is often dominated by species from within a few metres
431 of the sampling location, as mosses have the capacity to catch poorly distributed local pollen
432 (Bunting, 2003). A strong correlation has previously been found in Jotunheimen (1150-1500
433 m a.s.l.) between the abundance of *Salix* in the dwarf-shrub vegetation assemblage and the
434 frequency of *Salix* pollen in the pollen spectra (Caseldine, 1989). However, *Salix* pollen is
435 present throughout the 4000-year peat sequence in comparably small quantities ($\leq 1.6\%$). Due
436 to the close proximity of the tree line, it is possible that the arboreal component dominates the
437 pollen profile so heavily that it masks non-arboreal species in the profile, suggesting that even
438 the smallest signal of *Salix* pollen could indicate local presence of the species.

439 Additionally, the previously reported encroachment of shrubs affecting the higher elevations
440 of Galdhøpiggen (≥ 1550 m a.s.l.) in response to warming in the recent decades (Hallang et al.,
441 2020) is not evident from the modern peat- and moss samples. The shrub cover near the coring
442 site has likely not changed significantly in the past 14 years, and samples from the mire at 1000
443 m a.s.l. are not reflecting the changes at higher elevations.

444 Several species that are considered indicative of certain environmental conditions are present
445 in this zone. Previous studies conducted in Jotunheimen demonstrate strong correlations
446 between the abundance of indicator taxa in tundra vegetation and their representation in the
447 pollen spectrum (Pardoe 2006, 2014). Local non-arboreal taxa that produce little amounts of
448 pollen, such as *Empetrum* and *Salix*, were found to be accurate indicators of the composition
449 of local alpine plant communities above the treeline. Kuoppamaa et al. (2009) listed a number

450 of taxa that are linked to disturbance from land-use change in northern Fennoscandia; the
451 following also appear in our pollen profile: *Epilobium*, *Filipendula*, *Plantago major*,
452 *Ranunculus acris*-type and *Rumex acetosa/acetosella*. In Table 1, we have compiled a list of
453 pioneer species and species characteristic of mature vegetation assemblages on Galdhøpiggen
454 today.

455 The species dominating the pollen spectra in this zone are largely characteristic of the
456 present-day sub-alpine vegetation belt (Table 1). Several open-ground and disturbance
457 indicators, such as *Rumex acetosa/acetosella* type and *Filipendula* (Kuoppamaa et al., 2009)
458 are also present. The most likely Ranunculaceae species in the area is *Ranunculus acris*,
459 whilst the common Caryophyllaceae species is *Silene dioica*; both occur in the ‘tall herb’
460 communities in the sub-alpine belt, and extend into the low-alpine belt (John Matthews,
461 2021, personal communication). The pollen of both families is found in the moss polster.
462 Poaceae pollen is represented in the moss polster in higher quantities than throughout most of
463 the sequence; the common local Poaceae species is the alpine meadow-grass (*Poa alpina*),
464 another light-demanding pioneer species. The vegetation near the mire was recently disturbed
465 in 2004, when the road leading up the slope was asphalted, creating roadside verges suitable
466 for colonisation by pioneers (Matthews et al., 2018). However, no major disturbance events
467 in the surrounding landscape, such as clearing of the woodland or wildfires, have occurred in
468 the period 2000-2018, and no disturbance indicator is represented by unusually high amounts
469 of pollen in this zone. *Mid-Holocene pine-dominated mixed woodland (c. 4300-3400 cal. yr*
470 *BP)*

471 The altitude of the present-day tree line on Galdhøpiggen was covered by a local pine-birch
472 woodland between c. 4300-3400 cal. yr BP. The relative abundance of pine pollen for most of
473 the period exceeds the contemporary values by 50%, and indicates local dominance. PARs are
474 up to 10 times higher than estimated for 2000 AD, and indicate a dense pine forest (Table 2).
475 This suggests relatively warm summer temperatures (likely exceeding contemporary values) at
476 this altitude suitable for abundant pine growth, and the advancement of the pine tree line. Aas
477 and Faarlund (1988) suggest that that pine tree lines were 200 m higher (at 1200 m a.s.l.) in
478 Jotunheimen between (5000-2500 cal. yr BP), and c. 150 m higher than today towards the end
479 of this period.

480 Further, past climatic reconstructions of the area have indicated a decrease in glacial extent
481 between c. 4000-3000 cal. yr BP (Matthews and Dresser, 2008), and models suggest increased

482 mean annual ground- and surface temperatures at higher altitudes on Galdhøpiggen (up to 1458
483 m a.s.l.) that remain above 0°C during this period (Lilleøren et al., 2012; Winkler et al., 2021).
484 Higher temperatures, supported by the high relative abundance and PAR of pine pollen,
485 certainly would have influenced the extent of regional permafrost. Combining the evidence
486 from our pollen study with wider literature, we assume that the lower limit of permafrost
487 reached above 1500 m a.s.l. (Figure 5).

488 Whilst *B. pubescens* also appears locally present at 1000 m a.s.l., the relative abundance of its
489 pollen remains below the present-day values (2000-2014 AD) throughout. PAR, however,
490 exceeds the modern (2000 AD) value during most of this period (Table 2). The lower relative
491 abundance values could be due to the substantial dominance of pine pollen in the profile, as
492 PARs suggest a more abundant birch presence. Moreover, a study combining pollen data with
493 macrofossil evidence suggests that a subalpine birch zone has prevailed above the pine tree line
494 during the period 9000-2500 cal. yr BP, and despite the advanced pine tree lines, pine did not
495 represent the upper forest limit at any point during this time (Aas and Faarlund, 1988). It is
496 difficult to determine whether downy birch reached above the pine tree line on Galdhøpiggen
497 during this period without incorporating macrofossil evidence, but birch was most likely a
498 component of the pine-dominated mixed woodland at 1000 m a.s.l.

499 A woodland presence is further supported by the highest relative abundance of shade-preferring
500 Filicales spores (Kuoppamaa et al., 2009). The only common Filicales species at this altitude
501 today is *Gymnocarpium dryopteris*, a fern that prefers shady north-facing slopes and forms a
502 continuous carpet under birch trees (Matthews et al., 2018). The pollen of *Geranium*, which is
503 commonly found in the understorey today, is also present. Other trees were absent from the
504 woodland at this altitude, with *Alnus* pollen being regional, and *Quercus* and *Tilia cordata*
505 pollen derived via long-distance transport (Lisitsyna et al., 2011).

506 However, several disturbance- and open ground indicating species are also present throughout
507 this period. *Plantago media/major* occurs exclusively during this period, whilst Asteraceae,
508 *Filipendula* and *Rumex acetosa/acetosella* type exhibit their highest relative abundances in the
509 pollen profile, and Poaceae peaks in this zone. Several light-demanding Asteraceae species
510 grow in the sub-alpine and low alpine belts today, including *Hieracium* spp., *Achillea*
511 *millefolium*, *Solidago virgaurea* and *Gnaphalium norvegicum*. It is also notable that from
512 around 3700 cal. yr BP, there is an increase in light-demanding shrub pollen (*Betula nana*,
513 *Empetrum nigrum*, *Vaccinium* spp. and *Salix* spp.) (Robbins and Matthews, 2014). Whilst the

514 shrub pollen might have originated from the surface mire vegetation, the high relative
515 abundance of light-demanding herb pollen suggests that the mixed woodland may not have
516 been as dense as indicated by pine PARs. Overall, the species present during this period are
517 comparable to the mature vegetation assemblages of the present-day sub-alpine belt on
518 Galdhøpiggen (Table 1).

519

520

521 *Pine retreat and descent of the low-alpine zone (c. 3400 – 1700 cal. yr BP)*

522 The progressive decline in relative abundance and PAR of pine pollen between c. 4330-3000
523 cal. yr BP coincides with the gradual decline in modelled temperatures in southern Norway.
524 Modelled July temperatures were 1°C higher in 4500 cal. yr BP compared to present day (1961-
525 1990 mean) values; by c. 3000 cal. yr BP, the temperatures had declined and resembled present-
526 day values (Lilleøren et al., 2012). The heat flow model by Lilleøren et al. (2012) is based on
527 studies examining pollen, macrofossils and chironomids from lake sediments, as well as the
528 deposition rate of speleothems in Scandinavia, and the model is calibrated using modern
529 borehole temperatures, including those recorded on Galdhøpiggen. Climatic cooling during this
530 period is also suggested by the concurrent increase in downy birch pollen at the expense of
531 pine. Relative pollen abundance indicates local dominance and PARs are indicative of open
532 birch woodland for most of this period, suggesting that the conditions became cooler (and
533 possibly wetter), which benefits birch rather than pine.

534 By c. 3000 cal. yr BP, pine pollen reaches its lowest relative abundance in the entire profile,
535 coinciding with the decline of total arboreal pollen to its lowest level. Relative abundance and
536 PAR suggest that pine was not present within one kilometre of the coring site at the time, whilst
537 downy birch retains local dominance. Simultaneously, shrubs collectively reach their highest
538 relative abundance in the entire sequence, suggesting that the landscape at 1000 m a.s.l. was
539 becoming more open.

540 The synchronous increase in light-demanding species that characterise present-day low- and
541 mid-alpine vegetation belts, such as *Betula nana*, *Empetrum*, *Vaccinium* spp., and *Salix* spp.
542 Could indicate a possible descent of the low-alpine vegetation belt in response to colder
543 temperatures. The timing of the pine retreat and shrub encroachment corresponds to a cold
544 period of glacial expansion (Smørstabbtindan IV, 17 km from our site) between 3200-2550 cal.

545 yr BP (Matthews and Dresser, 2008); and a drop in modelled ground temperatures on
546 Galdhøpiggen by 0.2°C in the low alpine belt, and by 0.5°C in the mid-alpine belt between
547 4000 and 3000 cal. yr BP (Lilleøren et al., 2012). Moreover, Bjune (2005) reported a decline
548 in arboreal pollen and the opening of the landscape at 1309 m a.s.l. due to cooler conditions in
549 E Jotunheimen between 4950-2700 cal. yr BP.

550 All shrubs in our profile exhibit relative pollen abundance values that exceed the modern-day
551 values, illustrating a scenario where the sampling site was covered by denser stands of dwarf
552 shrubs at the expense of trees. Furthermore, *Epilobium angustifolium*, a light-preferring species
553 often occurring on sites following disturbance such as windthrow of trees or vegetation dieback
554 due to drought (Myerscough, 1980), appears in the profile at c. 3300 cal. yr BP in small
555 quantities (0.7%). Other disturbance indicators, such as *Rumex acetosa/acetosella* type,
556 Ranunculaceae, Caryophyllaceae (likely *Silene dioica*) and Asteraceae are also present.
557 Simultaneously, the proportion of shade preferring Filicales spores remains low.

558 The pollen diagram (Figure 3) indicates signs of climatic warming between 2800-1900 cal. yr
559 BP, as the relative abundance of arboreal pollen begins to recover whilst the proportion of
560 shrub pollen declines. The relative abundances of pine- and downy birch pollen indicate local
561 presence of pine and birch dominance. However, the PARs of pine and downy birch remain
562 low between 2500-1700 cal. yr BP, indicating a merely sparse local presence. This could be
563 due to the increase in cooler and more humid periods from 2500 cal. yr BP to present, resulting
564 in depressed tree lines and low pollen production (Aas and Faarlund, 1988). Matthews and
565 Dresser (2008) identified numerous cold periods of glacial expansion in the area from c. 3000
566 cal. yr BP to present day, including between 2350-1700 cal. yr BP. Modelled July temperatures
567 for southern Norway also decline further, remaining approximately 0.1-0.3°C lower than the
568 1961-1990 mean from 2000 cal. yr BP until c. 1900 AD (Lilleøren et al., 2012). Such conditions
569 reflect a period suitable for permafrost aggradation and the possible depression of the limit of
570 sporadic permafrost to altitudes lower than today (Figure 5). According to Lilleøren et al.
571 (2012), however, the lower limit of permafrost on Galdhøpiggen never reached below 1200 m
572 a.s.l. during the Holocene, suggesting that our coring site (1000 m a.s.l.) was free of permafrost
573 throughout this period.

574

575

[Insert Figure 5 here]

576

577 *Pine decline and the establishment of birch-dominated open woodland (c. 1700 cal. yr BP-*
578 *2000 AD)*

579 The topmost zone of the pollen profile covers c. 1700 years, and represents very low peat- and
580 pollen accumulation rates. The relative pollen abundances of the main arboreal species indicate
581 that from 1700 cal. yr BP to 2000 AD, downy birch was locally dominant, whilst pine
582 fluctuated close to the threshold of local presence, remaining regionally present throughout
583 most of this period (Table 2). Relative pollen abundances describe the local arboreal
584 composition in 2000 AD accurately, demonstrating that pine was locally present (26%) and
585 downy birch dominated (36%). PARs, however, are low for both species, fluctuating around
586 the threshold value for sparse presence, and suggest that neither was present within 1-km radius
587 from c. 600 cal. yr BP to 2000 AD. This is clearly an underestimation, as downy birch was
588 locally established in the 1980s, and pine was growing c. 200 m from the coring site by 2000
589 AD (Hallang et al., 2020). Therefore, the relative abundance of downy birch and pine pollen
590 can be considered as the more accurate indicator of local presence during this period.

591 The discrepancy between PARs and evidence from the area could indicate that the PARs in the
592 top half of the core are not reliable, and their accuracy might be improved by incorporating
593 more radiocarbon dates. Alternatively, the underestimation of arboreal PARs in the recent
594 millennia could be caused by retreated tree lines and lower pollen production due to continuing
595 cooler temperatures. Based on the consistently low relative abundance of pine pollen, the pine
596 tree line was likely lower than today between c. 1700-170 cal. yr BP, whilst the climatic
597 conditions remained more suitable for downy birch growth at 1000 m a.s.l. This scenario is in
598 accordance with two longer periods of glacial expansion between 1400-750 and 500-0 cal. yr
599 BP (Matthews and Dresser, 2008). The latest cold period also covers the Little Ice Age (LIA),
600 which peaked around 1750 AD to the end of the 19th century in southern Norway (Lilleøren et
601 al., 2012). Lowest simulated ground temperatures occurred c. 250 years BP, and the lower limit
602 of shallow permafrost is estimated to have reached as low as 1250 m a.s.l. (Lilleøren et al.,
603 2012). Unfortunately, due to the coarse resolution of our pollen profile caused by low peat
604 accumulation rates, the effects of the LIA are not detectable. However, our results indicate that
605 1700-170 cal. yr BP was likely a cold period with a low altitudinal pine tree line and a possibly
606 depressed permafrost limit.

607 Non-arboreal pollen also signals a more open landscape from 1690 cal. yr BP. The pollen of
608 shrub species indicative of dwarf shrub tundra retains high values from 1690 cal. yr BP to 2000

609 AD. Light-demanding *Betula nana* is the dominant shrub in the landscape, and *Salix*,
610 *Empetrum* and *Vaccinium* are present throughout. Disturbance-indicating herbaceous species
611 and pioneers, such as Asteraceae, *Filipendula*, Ranunculaceae, Poaceae and *Rumex*
612 *acetosa/acetosella* type are represented throughout by small quantities of pollen, and
613 *Epilobium angustifolium* is briefly found again at c. 2003 AD. However, none of the
614 disturbance indicator species show significant peaks in the pollen profile at any time.
615 Therefore, in this case, it is difficult to confidently identify significant periods of increased
616 disturbance based on the indicator species alone.

617 From c. 100 cal. yr BP, climatic conditions became warmer. Hipp et al. (2012) estimated that
618 the lower limit of permafrost on Galdhøpiggen has moved up by 200 m since 1860. In south-
619 east Norway, birch tree lines advanced by 40 m between 1918 and 1969 (Aas, 1969), and an
620 increase in tundra species richness at altitudes between 1600–1800 m a.s.l. on Galdhøpiggen
621 has been recorded between 1930 and 1998 (Klanderud and Birks, 2003). By 2000 AD, pine
622 had established its altitudinal limit at 1000 m a.s.l. alongside downy birch. It is also notable
623 that *Picea abies* pollen appears in the profile at around 800 cal. yr BP, several hundred years
624 later than estimated in other pollen studies in the area (e.g. Barnett et al., 2001), but remains
625 “regional” up to the present day (Table 2). The closest spruce stands are currently c. 2 km from
626 the site, growing at an altitude 200 m lower than the tree line.

627

628 **Conclusions**

629 The late-Holocene vegetation dynamics on the slope of Galdhøpiggen were reconstructed by
630 employing a combination of indicators of species’ local presence. From c. 4350 cal. yr BP until
631 present, the area around 1000 m a.s.l. has been dominated by two arboreal species, *Betula*
632 *pubescens* and *Pinus sylvestris*. Between c. 4300 and 3400 cal. yr BP, the area was covered by
633 a pine-dominated mixed woodland, suggesting that the climatic conditions were warmer than
634 today. The lower limit of permafrost was likely above 1500 m a.s.l. From c. 3400–3000 cal. yr
635 BP, pine began retreating to lower elevations, accompanied by the descent of the low-alpine
636 shrub-dominated vegetation belt in response to climatic cooling. This was a period of colder
637 temperatures and permafrost aggradation. The colder period continued through 1700 – 170 cal.
638 yr BP, as pine retained a sparse presence, and an open downy birch woodland dominated the
639 landscape at this altitude. The lower limit of permafrost likely reached lower altitudes than
640 today. From c. 170 cal. yr BP onwards, the conditions became warmer and pine had re-

641 established its local presence at 1000 m a.s.l. by 2000 AD. Downy birch remained locally
642 present throughout this period, and the lower limit of permafrost moved upslope to its present-
643 day altitude of 1450 m a.s.l.

644 The complementing techniques used to determine the local presence of species here (relative
645 pollen abundance, PAR, and indicator species) can sometimes produce conflicting results,
646 especially when the profile is heavily dominated by arboreal pollen. Therefore, the combined
647 use of several methods still requires an appreciation of the strengths and weaknesses of the
648 individual methods.
