48	Abstract
49	The Burrows-Wheeler Transform (BWT) is a string transformation tech-
50	nique widely used in areas such as bioinformatics and file compression.
51 52	Many applications combine a run-length encoding (RLE) with the BWT
52	in a way which preserves the ability to query the compressed data ef-
54	ficiently. However, these methods may not take full advantage of the compressibility of the BWT as they do not modify the alphabet or-
55	dering for the sorting step embedded in computing the BWT. Indeed,
56	any such alteration of the alphabet ordering can have a considerable
57	impact on the output of the BWT, in particular on the number of
58	runs. For an alphabet Σ containing σ characters, the space of all al-
59	phabet orderings is of size σ !. While for small alphabets an exhaustive investigation is possible. Indian the entired ordering for larger alpha
60 61	investigation is possible, finding the optimal ordering for larger alpha- bets is not feasible. Therefore, there is a need for a more informed
61 62	bets is not reasible. Therefore, there is a need for a more informed

2 Heuristics for the RLBWT Alphabet Ordering Problem

search strategy than brute-force sampling the entire space, which motivates a new heuristic approach. In this paper, we explore the non-trivial cases for the problem of minimizing the size of a run-length encoded BWT (RLBWT) via selecting a new ordering for the alphabet. We show that random sampling of the space of alphabet orderings usually gives sub-optimal orderings for compression and that a local search strategy can provide a large improvement in relatively few steps. We also inspect a selection of initial alphabet orderings, including ASCII, letter appearance, and letter frequency. While this alphabet ordering problem is computationally hard we demonstrate gain in compressibility.

Keywords: Alphabet ordering, Burrows-Wheeler Transform, Compression, Local search, Random sampling, Run-Length Encoding

1 Introduction

31 The Burrows-Wheeler Transform (BWT), originally known as block-sorting 32 compression, is a text transformation scheme which computes a permutation 33 of an input string of data (Burrows & Wheeler, 1994). The transformation 34 is achieved by sorting the matrix of all circular shifts (rotations) of a string 35 into lexicographic order and extracting the last column from the matrix. The 36 37 algorithm can be implemented using a suffix array data structure with over-38 all linear time complexity. Furthermore, using the index of the original string 39 in the sorted matrix, the transform can be inverted in linear time, enabling 40 efficient recovery of the input data. Hence the BWT is applicable to lossless 41 compression activities, notably as a pre-processor preparing the data for com-42 pression. An important property of the transform is that it groups together 43 characters with similar context, which are often identical characters, that is, 44 it has a tendency to rearrange a string of characters into runs of the same 45 character.

46 The computational efficiency of this remarkably simple innovation has 47 enabled wide-ranging applications related to the indexing, searching, and com-48 pression of text (Adjeroh, Bell, & Mukherjee, 2008). The BWT is implemented 49 in the popular open-source file compressor Bzip2 (Seward, 1996), as well as 50 in bioinformatic sequence alignment utilities including Bowtie2 (Langmead & 51 Salzberg, 2012), BWA (H. Li & Durbin, 2009), and SOAP2 (R. Li et al., 2009), 52 and additionally in image compression (Syahrul, Dubois, Vajnovszki, Saidani, 53 & Atri, 2008). 54

A large amount of research has been conducted to improve the space complexity of the BWT and common data structures used to query the BWT such as the FM-index. Such improvements include applying run-length encoding
(RLE) to the transformed text or other structures.

This was first investigated by Mäkinen and Navarro as the run-length
encoded FM-index (RLFM-index) (Mäkinen & Navarro, 2005) and improved
on (Sirén, Välimäki, Mäkinen, & Navarro, 2008), including much more recently

- 63
- 64
- 65

by Gagie, Navarro, and Prezza (Gagie, Navarro, & Prezza, 2020), using a run-length encoded BWT (RLBWT) and suffix array samples (r-index). The r-index provides a full-text searchable index in O(r) space, where r is the number of runs in the BWT, and has been of interest for the finding maximal exact matches step in bioinformatics read alignment (Rossi et al., 2022).

The order of the characters in the compressed BWT text heavily relies on the alphabet ordering used to sort the suffixes. By varying the alphabet ordering used for the BWT, the output can be influenced to further group characters, improving over the extended ASCII alphabet ordering which is typically implemented in software utilities.

Alphabet orderings for the BWT have been considered by Chapin and Tate (Chapin & Tate, 1998), where both a hand-picked ordering and orderings created from a heuristic algorithm were used and tested on both text and imaging data. It is suggested that placing similar characters together in the alphabet (vowels, consonants, and punctuation) yield greater compression over ASCII in their pipeline involving the BWT.

Related BWT research has been conducted which, for a given ordered al-31 phabet Σ , investigate a variety of non-lexicographic orderings of Σ^* , providing 32 33 tailored methods to order the set of strings rather than reordering the al-34 phabet. The ABWT is based on alternating lexicographical order (Giancarlo, 35 Manzini, Restivo, Rosone, & Sciortino, 2018, 2020), which flips the order re-36 lation between \langle and \rangle at each subsequent position during the scan of two 37 strings being compared. The V-BWT is based on V-order which repeatedly 38 deletes a V-type letter and at the penultimate stage of equality applies co-39 lexorder (Daykin & Smyth, 2014). The D-BWT, which is applied to degenerate 40 (also known as indeterminate) strings where each string position consists of a 41 nonempty subset of letters over Σ , determines a lex-extension to sort the con-42 jugates (Daykin & Watson, 2017). The binary B-BWT applies binary block 43 order and yields not one but twin transforms (Daykin et al., 2016). 44

Ordering texts within a collection has also been examined (Bentley, Gibney, 45 & Thankachan, 2020; Cazaux & Rivals, 2019; Cox, Bauer, Jakobi, & Rosone, 46 2012), which involves adding a unique separator to each text in the collection. 47 A notable result is that finding a minimal number of runs r by ordering of the 48 texts can be done in linear time (Bentley et al., 2020; Cazaux & Rivals, 2019), 49 50 though this approach does not perform reordering of the alphabet within each text. Pibiri (2023) has implemented a graph-based algorithm for ordering the 51 52 biological sequences within a collection such that the k-mers can be efficiently 53 stored in a hash table. The ordering is chosen to ensure that the corresponding 54 k-mer counts can be compressed using RLE while still enabling queries of the 55 k-mer counts.

Reordering the alphabet to minimize r has been shown to be APXhard (Bentley et al., 2020; Gibney, 2021). In addition, Bentley, Gibney, and Thankachan showed that finding an alphabet ordering to ensure r < t for a given threshold t is NP-complete (Bentley et al., 2020). We also know that r is limited to no more than twice the number of runs in the original text

Heuristics for the RLBWT Alphabet Ordering Problem

(Mantaci, Restivo, Rosone, Sciortino, & Versari, 2017), providing a bound to the quality of any worst case alphabet ordering.

While the theoretical hardness of choosing the best alphabet ordering is clear, we still know little about the potential to efficiently and substantially improve on ASCII orderings. In this paper, we first randomly sample widely from the space and then to use heuristic search to understand more about potential improvements to the alphabet ordering which could be made cheaply and quickly, reducing the size of RLBWT compressed texts.

22 We show that most randomly sampled alphabet orders achieved little im-23 provement in size reduction. However, we show that a First-Improvement local 24 search can quickly improve on randomly sampled alphabet orderings, even 25 when using a limited number of steps. Additionally we consider initializing 26 the search with promising initial orderings to seed the search, taking into ac-27 count character frequency and appearance, and showing how they affect the 28 speed of improvement of the search over time. We also evaluate a variety of 29 operators for directing the search and find that a combined search strategy 30 of two standard operators SWAP and INSERT (Eiben & Smith, 2015) may 31 improve the local minima depending on the order of their use. We further 32 consider varied orderings of the neighbors of an alphabet ordering, searching 33 34 them lexicographically, reverse-lexicographically, and randomly (Section 4.2).

Section 2 introduces and formalizes the problem and terminology. We discuss the special cases for small alphabets in Section 3, and First-Improvement local search methods for larger alphabets in Section 4. Our experimental setup is discussed in Section 5.1. A detailed discussion of our results can be found in Section 5. We summarize our contribution in Section 6 and provide an overview of future research directions.

2 Notation, Problem Definition, and Modeling

In this section, we provide formal definitions for BWT and RLE with examples
given for the key definitions. We also formally state the considered optimization problem. For each of the following definitions it is assumed that we have
the following:

49 An alphabet Σ , is an ordered non-empty set of unique characters 50 $\{x_0, x_1, \dots, x_{\sigma-1}\}$, where $x_0 < x_1 < \dots < x_{\sigma-1}$ and $x_i < x_j$ implies x_i pre-51 cedes x_j . The standard 'Roman' alphabet ordering as implemented in the 52 ASCII table is denoted as Σ_R . 53 A string $\mathbf{s} = c_0 c_1 \dots c_{n-1} = \mathbf{s}[0, n-1]$ over an alphabet Σ is a finite

A string $\mathbf{s} = c_0, c_1, \ldots, c_{n-1} = \mathbf{s}[0..n-1]$ over an alphabet Σ , is a finite sequence of characters of length $n = |\mathbf{s}|$, such that $c_i \in \Sigma, c_i = \mathbf{s}[i]$. The individual characters c_i will be denoted as $\mathbf{s}[i]$ subsequently.

2.1 Key Definitions

A BWT (Definition 2) is computed by first forming a Burrows-Wheeler Matrix (BWM, Definition 1) – the sorted list of strings formed by all *cyclic rotations*

61 62

54

55

56 57

58 59

60

42

- 63
- 64
- 65

of a string – and taking the last column of the matrix. This has a tendency to group identical characters together and is useful for compressing with an RLE.

Alphabet reordering allows us to impact the ordering of the rows within a BWM. For any *string* s of length n with an *alphabet* Σ of size σ , there is a total of σ ! possible alphabet orderings.

Definition 1 (Burrows-Wheeler Matrix / BWM) Let s and s' be two strings over the same alphabet Σ . The string s' is said to be a *cyclic rotation* of s if and only if there exists two strings u and v with |v| = 1 such that s = uv and s' = vu. The lexicographically ordered, row-arranged set of all *cyclic rotations* of s^{\$} sorted according to the order of Σ , with \$ least in Σ , and denoted as $BWM(s, \Sigma)$ is the BWM of s. The BWM of s without adding an implicit \$ is denoted as $BWM_*(s, \Sigma)$.

It should be noted that we do not consider the end marker (normally \$) to be movable within the alphabet ordering, instead always appearing first as an implicit least character. We illustrate Definition 1 in the following example. For the sake of simplicity we use the standard 'Roman' alphabet ordering Σ_R .

Example 1 Let a string s = cacatcg and using Σ_R , the BWM is as follows, where F and L denote the first and last columns of the matrix respectively:

Using Definition 1 we can now formally define a BWT as the last column L of the BWM.

Definition 2 (Burrows-Wheeler Transform / BWT) For an input string \boldsymbol{s} of length n and an alphabet ordering Σ , we define the BWT as $BWT(\boldsymbol{s}, \Sigma) = BWM(\boldsymbol{s}, \Sigma)[i, n-1]$, $\forall i$ such that 0 < i < n-1. The BWT of \boldsymbol{s} without implicitly adding a \$ is denoted as $BWT_*(\boldsymbol{s}, \Sigma)$.

The BWT for the string in Example 1 with the ordering Σ_R is therefore obtained from the last column L of the BWM as gcc atca. The BWT can be computed from the suffix array (SA) of s as follows:

$$L[i] = \begin{cases} \$, & \text{if SA[i]=0} \\ s[\text{SA[i]-1]}, & \text{otherwise.} \end{cases}$$

Heuristics for the RLBWT Alphabet Ordering Problem

The suffix array may be computed in linear time (Kim, Sim, Park, & Park, 2005; Ko & Aluru, 2005) and enables BWT construction with the same time complexity. Inversion of the BWT may be achieved through the last-first mapping (Burrows & Wheeler, 1994). For a string s, the BWT(s, Σ) may be updated for a modified string s', BWT(s', Σ) in sub-linear time (Kempa & Kociumaka, 2022). Recent developments have led to an efficient algorithm for directly constructing the RLBWT (Nishimoto, Kanda, & Tabei, 2022) in $O(n + r \log r)$ time but O(n) time for strings where $r = O(n/\log n)$, and working space $O(r \log n)$ of bits.

Definition 3 (Run-Length Encoding / RLE) For a string s, u is a substring of s if there are possibly empty strings a and b such that s = aub, and u is bounded by the indexes (i, j) where $0 \le i \le j \le n-1$. Let $p_0 p_1 p_2 \dots p_{n-1}$ be a sequence of substrings of s such that $s = p_0 p_1 p_2 \dots p_{n-1}$ and $p_i[j] = p_i[k] \forall j, k < |p_i|$ (i.e., each p_i is a sequence containing identical characters). RLE(s) is the string where each run of identical characters p_i in s is replaced by a single copy of that character and a count of the characters in the run. We denote the length of each run of characters in superscript, for instance: $\text{RLE}(s) = p_0[0]^{|p_0|} p_1[0]^{|p_1|} \dots p_{n-1}[0]^{|p_{n-1}|}$.

We illustrate Definition 3 with an example using Σ_R .

37 Example 2 Let a string $\mathbf{s} = cacatcg$ using Σ_R , The output L column of 38 $BWM(\mathbf{s}, \Sigma_R)$ is gcc\$atca. This is encoded as $RLE(BWT(\mathbf{s}, \Sigma)) = g^1c^2\$^1a^1t^1c^1a^1$, 39 $|RLE(BWT(\mathbf{s}, \Sigma))| = 14$.

We are interested in overall memory usage for the RLE, so each run is encoded as the byte (character) and then the length of the run up to 255. Any runs over 255 in length are encoded as additional bytes (Section 2.2). This is represented as |RLE(s)|.

To demonstrate the influence an alphabet ordering can have on the BWM, BWT and RLE, we consider the same example string using an alternative alphabet ordering.

Definition 4 (r) The number of maximal length runs in the BWT. For example, let s = acacacbbacbac and $\Sigma = a < b < c$. BWT_{*} $(s, \Sigma) = bccbccbcaaaaa$. As there are 7 runs in the BWT output, r = 7.

The r value for any BWT of a string is not necessarily less than the r value of a string itself. A classic example is the string mississippi\$ where the BWT is ipssm\$pissii which also shows that computing the BWT permutation of the input data does not necessarily make the data more compressible.

2.2 Problem Statement

We wish to investigate the sample space of alphabet orderings. Since reordering the alphabet to minimize the number of runs has been shown to be APX-hard, we will use and investigate different heuristics.

We evaluate the fitness of any new alphabet ordering Σ by the total length of its RLE. As we use the input data bytewise, the 'characters' in our alphabet are these bytes and not another encoding such as UTF. We do not use the total number of identical character runs in the BWT(r) as the fitness since we are interested in overall memory consumption of the representation. Each input file is read bytewise, so multi-byte (non-ASCII) characters are represented as more than one 'character' in the alphabet.

We encode the RLE as a sequence of byte pairs, with the first byte of each pair representing the run's character, and the second byte representing the length of the run. As the maximum value that may be represented in a byte is 255, any larger runs will be represented with multiple pairs of bytes.

We therefore seek to minimize the size of RLE for our tested texts.

RLBWT ALPHABET ORDERING PROBLEM **Input:** A string s of length n over an alphabet Σ of size σ **Output:** A reordering of Σ for $RLE(BWT(s, \Sigma))$ that minimizes $|RLE(BWT(s, \Sigma))|.$

3 Methods for Small Alphabets

3.1 Binary Alphabet Orderings

We consider the simplest non-trivial case where there are only 2 characters and show that when using the reverse of an alphabet ordering that r remains the same for both orderings for primitive strings.

Lemma 1 Let s be a binary string over $\Sigma = \{a, b\}$ of length n. Let $\Sigma_1 = a < b$, $\Sigma_2 = b < a$. Then $r(s, \Sigma_1) = r(s, \Sigma_2)$.

Proof Suppose s is primitive, then all of its conjugates are distinct (Petersen, 1996). Let $p = p_0 \dots p_{n-1}$ and $q = q_0 \dots q_{n-1}$ be two adjacent rows in BWM_{*}(s, Σ_1) such

Heuristics for the RLBWT Alphabet Ordering Problem

that p is lexicographically less than q. Assume that s contains two distinct characters (otherwise the claim is trivial), then let t be the minimal index such that $p_t \neq q_t$, thus $p_t = a < b = q_t$. On the other hand in BWM_{*} (s, Σ_2) , q is lexicographically less than p. The argument holds for all pairs of adjacent rows showing that the two matrices are flipped row-wise, hence have the same r value.

In the case that s is not primitive and has the form u^k , k > 1, then all groups of k identical and adjacent rows in $BWM_*(s, \Sigma_1)$ will likewise be adjacent in $BWM_*(s, \Sigma_2)$ after the flipping.

Observe that using transitivity the argument on reversing an alphabet extends to an arbitrary finite alphabet which motivates our search for effective orderings. We illustrate concepts with the following ternary example:

Example 4 (Ternary primitive)

Let
$$s = aabbcc$$
, and $\Sigma_1 = a < b < c$

BWT_{*} $(\boldsymbol{s}, \Sigma_1) = caabcb, r(\boldsymbol{s}, \Sigma_1) = 5.$ In the case with $\Sigma_2 = c < b < a$:

$$BWM_{*}(s, \Sigma_{2}) = \begin{cases} F & L \\ c & c & a & b & b \\ c & a & a & b & b & c \\ b & c & c & a & a & b \\ b & b & c & c & a & a \\ a & b & b & c & c & a \\ a & a & b & b & c & c & a \end{cases}$$

46 BWT_{*} $(s, \Sigma_2) = bcbaac, r(s, \Sigma_1) = 5.$ 47 Thus both orderings have the same r value.

Example 5 (Ternary non-primitive) Let s = abcabc, and $\Sigma_1 = a < b < c$:

$$BWM_{*}(\boldsymbol{s}, \Sigma_{1}) = \begin{vmatrix} F & L \\ a & b & c & a & b & c \\ a & b & c & a & b & c \\ b & c & a & b & c & a \\ b & c & a & b & c & a \\ c & a & b & c & a & b \\ c & a & b & c & a & b \\ c & a & b & c & a & b \end{vmatrix}$$

Likewise for $\Sigma_2 = c < b < a$ it is trivial to see that the r value of both orderings is the same.

Heuristics for the RLBWT Alphabet Ordering Problem 9

$$BWM_{*}(s, \Sigma_{2}) = \begin{vmatrix} F & L \\ c & a & b & c & a & b \\ c & a & b & c & a & b \\ b & c & a & b & c & a \\ b & c & a & b & c & a \\ a & b & c & a & b & c \\ a & b & c & a & b & c \end{vmatrix}$$

3.2 Exhaustive Search on Biological Data

For small alphabets it may be feasible to search through all possible alphabet orderings to find the one(s) that provide(s) the best RLBWT compression of the data.

For example, in the case of genomic data, such as a collection of the gen-ome sequences of many E. coli bacteria, we could expect a limited 4-letter alphabet $\{a, c, g, t\}$ representing nucleotides giving 24 possible alphabet order-ings. For such a collection, the genomes would share much in common, and the RLBWT of a concatenation of these sequences should capture the commonal-ities effectively. However, almost all bioinformatics algorithms choose to use the ASCII ordering a < c < q < t, even though this may not provide the best results.

We took a collection of 150 diverse E. coli genomes from NCBI and com-pared the compression obtained using each possible alphabet ordering. The ordering t < c < a < g provided the best compression (-91.627% change), and the worst ordering was c < q < t < a (-91.576% change) – for further details see Table 1. Although an exhaustive search through all possible alphabet or-derings is often prohibitively expensive, this example demonstrated that better choices can make improvements, and motivated our investigation to find such orderings and examine the search space of orderings for its properties.

Table 1 Percentage difference in file size using each of the 24 alphabet orderings for the
alphabet $\{a, c, g, t\}$ for the 150 concatenated *E. coli* data files when using the RLBWT.

Min % Change	Max % Change	Mean	Std
-91.576	-91.627	-91.597	0.02

4 Methods for Larger Alphabets

Since the permutation space of the alphabet ordering for an alphabet of size σ is σ !, in most practical cases, exhaustive enumeration of all alphabet orderings is not a feasible approach. We therefore consider different variants of a First-Improvement local search for larger alphabets. We use different types of texts, considering a variety of different text lengths and alphabet sizes. The main goal of our experimental analysis is to provide insights into the working principles

38

10 Heuristics for the RLBWT Alphabet Ordering Problem

of the considered methods for the given problem and to provide guidelines for their use. The considered algorithms are introduced in Sections 4.1 and 4.2.

4.1 Baseline: Random Sampling

We use uniform random sampling as a baseline approach to inspect the statistical distribution of potential compression gains that could be made by reordering the alphabet. The results are compared with the results of First-Improvement local search as described in the next section.

An interesting property of random sampling is that the mean number of improvements to be expected is actually bounded by the logarithm of number of trials. Indeed, as every new sample (i.e., alphabet order) is independent of the previous samples, the chance of obtaining a better compression after Tsampling steps with a new sample would be $P_{improving(T)} = \frac{1}{T+1}$, should the compression value obtained be unique for every sampling event. Therefore, the 29 expected number of successive improvements in compression using T random 30 samples would be simply given by $\sum_{i=0}^{T} \frac{1}{i+1} = O(\log T)$. In practice, the compression value will belong to a limited set of integer values, and each 31 32 new sample result may just be equal to the best compression value obtained 33 so far. As such, the actual chance $P_{improving}(T)$ after T samples to improve 34 compression is less than $\frac{1}{T+1}$, and $O(\log T)$ becomes an upper bound for the 35 total number of improvements expected from T random samples. 36

4.2 First-Improvement Local Search

39 We consider a variant of First-Improvement Local Search as our main optim-40 isation approach. Pseudocode for this approach is given in Algorithm 1. The 41 algorithm takes as input a text and its alphabet. It starts from some initial 42 alphabet ordering π (line 3) and tries to improve the ordering until a provable 43 local optimum is reached (line 15). In each loop it considers all neighbors of 44 45 the current ordering π in a given order (line 7). If an improvement is found 46 (line 8), the algorithm moves to the better ordering (line 10) and repeats the 47 process (updating the neighborhood as needed, line 11). The fittest ordering 48 is returned.

In our experiments, we consider 9 different initialization methods in line
of Algorithm 1 as discussed in Section 4.2.1. We also consider 12 different
neighborhoods as discussed in Section 4.2.2, leading to a total number of 108
algorithm configurations.

4.2.1 Initialization

We consider the following 9 initialization methods in line 3 of Algorithm 1.
With the exception of random initialization, all methods are deterministic and based on some heuristic or standard ordering from the literature.

12 Heuristics for the RLBWT Alphabet Ordering Problem

V < X < Y < Z. Other changes to the ordering such as '!' and '@' being swapped, and the '+-,.' rearrangement are also present in this ordering.

- Vowels: Vowels (aeiouAEIOU) are placed at the beginning of the ordering.
 Similar to the Chapin Tate ordering, the main aim is to explore if grouped punctuation and the consonant reordering really helps the problem, or if moving the vowels alone will yield a better initial ordering.
- FDA: The FDA algorithm was introduced to determine an alphabet ordering for a variant of the Lyndon factorization problem (Major et al., 2020). The main motivation to include this method is to explore if these orderings might be more generally useful for alphabet ordering problems on strings. It should be noted that FDA determines a partial alphabet ordering. A total ordering is produced from the partial ordering by topological sort.

For each of these orderings, we place the selected end marker character (usually \$) as least in the ordering when performing the BWT.

4.2.2 Local Search Neighborhoods

For the neighborhoods in lines 4 and 11 of Algorithm 1 we consider combinations of two standard operators for permutation sample spaces, namely SWAP (aka EXCHANGE) and INSERT (aka JUMP) (Eiben & Smith, 2015). SWAP picks two integers $0 \le i < j \le \sigma - 1$ and swaps the characters at positions *i* and *j*. INSERT picks two integers $0 \le i, j \le \sigma - 1$ with $i \ne j$. It moves the character at position *i* to position *j*, shifting all subsequent characters to the right.

Looking at the two operators in isolation we observe that SWAP yields a neighborhood of size $\sigma(\sigma - 1)/2$ while INSERT yields a neighborhood of size $\sigma(\sigma - 1)$. Both neighborhood sizes are quadratic in σ , the size of the alphabet.

We first consider both operators in isolation and investigate three different orderings of the neighbors in the neighborhoods:

- Random Order: Using a random order of the neighbors is the most common approach.
- Lexicographic Order (Lex): We hypothesize that it maybe be beneficial to first fix characters at the start of the ordering. We therefore consider the fixed lexicographic order of neighbors. For example, for SWAP we consider *i*-*j*-pairs in the following order: $(0, 1), (0, 2), ..., (0, \sigma 1), (1, 2), ..., (\sigma 2, \sigma 1)$. Any unspecified neighborhood ordering should be assumed to be LEX.
 - **Reverse Lexicographic Order (RevLex):** We consider the opposite case by reversing the lexicographic order given above.

Finally, we consider a combination of SWAP and INSERT. More precisely,
we first try all possible SWAPs followed by all possible INSERTs and vice versa.
For each of the two lists of neighbors we consider all three orders defined
above, ensuring that all SWAPs are sorted before all INSERTs (and vice versa)
as appropriate. If a combination of operators is used, the second operator will
only be used until an improvement is found. The algorithm then returns to
using the first operator.

5 Results and Discussion

5.1 Experimental Setup

All our experiments are run on Super Computing Wales² on a single node 18 (2x Intel(R) Xeon(R) Gold 6148 CPU @ 2.40GHz with 20 cores each) and Aberystwyth DCS cluster on a single node (2x Intel(R) Xeon(R) Gold 6248R CPU @ 3.00GHz with 48 cores each). As usual, we report the number of objective function evaluations rather than wall-clock time. 22

For each stochastic variant of First-Improvement local search, we report 23 statistics on the results of 20 independent runs. However, to avoid the distor-24 tion of our results due to different random starting points, all variants with 25 26 random initialization use the same 20 starting points which were randomly 27 determined prior to running our experiments. This way we can analyze the 28 effect of different neighborhoods on the same starting points without intro-29 ducing additional variables. For each run we report the number of function 30 evaluations as 'steps'. 31

We define C as the percentage change in file size relative to the uncompressed size (measured as a percentage in bytes):

$$C = \left(\frac{\text{Compressed Size} - \text{Uncompressed Size}}{\text{Uncompressed Size}}\right) \cdot 100 \tag{1}$$

We present C as raincloud plots (Allen et al., 2021) (a combination of a distribution, boxplot, and jittered point cloud) to give an indication of the density and shape of the sample space. A negative value for C demonstrates a reduction in size while a positive value demonstrates an increase in size. The smaller the value for C the better the compression. The number of steps presented is hitting time and not exhaustive checking of the neighbors.

5.2 Benchmarking

46 We use a standard benchmark for data compression for our analysis, namely 47 the Canterbury corpus (Arnold & Bell, 1997). Table 2 lists the different files 48 contained in the corpus, including the size of each file and the corresponding 49 alphabet size. The file kennedy.xls is excluded from our experiments for 50 technical reasons: our BWT implementation relies on a unique end marker 51 character and the alphabet size of 256 leaves no available character if the file is 52 used bytewise. We reorder the alphabet by mapping the input text characters 53 to new ones based on the order of characters in the alphabet. We then use the 54 SAIS suffix array implementation by Yuta Mori³ to compute the suffix array 55 56 (Ko & Aluru, 2005; Nong, Zhang, & Chan, 2011). Another implementation is 57 also provided in our repository but was not used due to speed. 58

We do not run to completion for some files in the corpus (for example: ptt5, sum, xargs.1) for some of the SWAP THEN INSERT and INSERT THEN SWAP

 Files in the Canterbury corpus with their size in bytes and the number of unique bytes in their alphabet

methods due to prohibitive runtimes. Instead we run to a limit of 10,000 steps as this is more than the maximum number of steps to outperform a random sample (Table. 5). A full list of the files and methods run until 10,000 steps only is available in our repository⁴.

5.3 Randomly Sampled Alphabet Orderings

We inspected the landscape of percentage change in compression that can be achieved using the RLBWT by changing the alphabet order, and sampled 240,000 alphabet orders uniformly at random (by Fisher-Yates shuffle) for each of the texts. We do this to learn more about the shape of the sample space and to understand whether there are many best orderings to be found or few.

The number of samples was chosen since it was large but remained tract-40 able to compute on a local machine (Intel(R) i7-8700K CPU @ 3.70GHz with 41 12 cores). To exemplify our findings, the results for files alice29.txt, sum 42 and fields.c are shown in Fig. 1. The number of samples may be few in 43 comparison with the very large σ ! space, however due to the smooth overall 44 distributions without outliers we can see that the sampling already gives a 45 clear picture of the shape of the space from which further random samples 46 would be obtained. The distributions are bell-shaped but not normally dis-47 tributed (scistats.normaltest Virtanen et al. (2020)), having a long thin tail 48 49 downwards where better solutions can be found.

These distributions demonstrate a spread of percentage compression for different alphabet orders, with the majority being sub-optimal choices and the sample space having only a thin tail of better choices. These figures also highlight the surprisingly good compression achieved by the ASCII ordering, lying far below most random choices of alphabet order, even for executable files such as sum. The full set of figures for all corpus files can be seen in our repository.

However, most texts in the corpus can be compressed to be smaller than the original by using the RLBWT, despite the fact that most randomly chosen

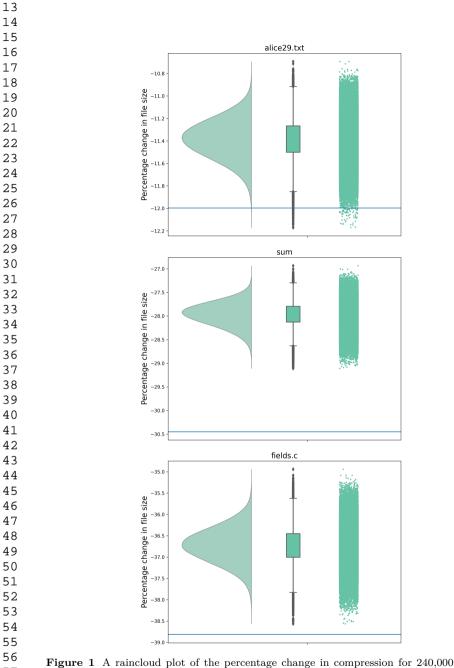

Figure 1 A raincloud plot of the percentage change in compression for 240,000 random
 samples of alphabet orderings used with the RLBWT for three of the corpus texts. Similar
 shaped distributions can be seen for the novel alice29.txt, SPARC executable file sum and C
 source file fields.c. Horizontal blue line represents the ASCII ordering, which outperforms
 most of the randomly sampled orderings.

Heuristics for the RLBWT Alphabet Ordering Problem

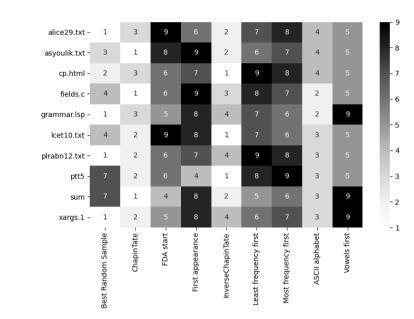

Figure 2 Ranking of each initialization method and the best randomly sampled ordering for each file before local search is applied.

alphabets are poor choices (See Tab. 3). This is true even with the worst choice of alphabet order. The best alphabet order found when randomly sampling for ptt5 reduced the file size by 74.207%. The file plrabn12.txt does not compress well and the best alphabet order sampled for this file increased the size by 1.019%, and ASCII performs worse than the best randomly sampled alphabet order.

While for most files, randomly sampled alphabet orderings may compress the size of the file somewhat, few sampled orderings improve on the ASCII alphabet ordering. In fact, several of the initialization ordering methods (Sec 4.2.1) also already outperform even the best of the randomly sampled orderings for many of the files. The heatmap in Figure 5.3 shows the rankings of the initialization orderings for the different files. The benefits of ASCII and Chapin Tate orderings can be seen clearly in this figure. It can also be seen from this figure that even after randomly sampling 240,000 orderings, the best of these is not good enough. Random sampling is therefore a too costly search strategy and necessitates another solution.

5.4 Improved Fitness with Local Search

In contrast to the compression obtained via random sampling of alphabet orders (Sec. 5.3), even the most simple of our local search methods – SWAP,
LEX – can achieve a better fitness value for our tested data. Fig. 3 shows the
contrast between the best solutions found during a local search (using the
SWAP operator) and the results of the random sampling. This figure shows

File	Min % Change	Max % Change	Mean	Std
alice29.txt	-12.171	-10.694	-11.385	0.172
asyoulik.txt	-0.533	1.028	0.324	0.177

xargs.1	CT	-7.783	CT	-12.042

alice29.txt, sum and fields.c. Other corpus files have similar plots, which can be seen in our repository. The large gap between their distributions indicates that there are excellent alphabet orderings that have not previously been sampled, even when sampling 240,000 orderings.

5.5 The Impact of Initialization on Local Search

50 When performing a local search, the initial alphabet order makes a difference
51 to the best solution that can be found by the local search using the SWAP
52 operator.
53 Tab. 4 shows which initialization ordering achieves the best compression

Tab. 4 shows which initialization ordering achieves the best compression when the search terminates at the local minimum or after 1000 steps. While randomly chosen orders are competitive if the search is terminated early after 1000 steps, ASCII, Chapin Tate, and Inverse Permutation Chapin Tate perform best if the search is allowed to complete.

58 The plots in Fig. 4 exemplify how the results improve over the time taken 59 by the search. A steep drop in the size of the file is observed followed by a large 60 number of steps until the local optima is reached. The initialization order that 62 leads to the best local minimum at the end of the search is not obvious at the

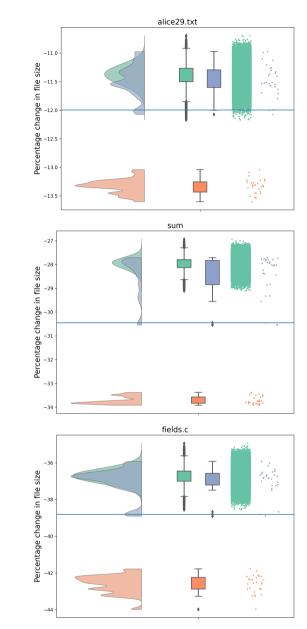

Figure 3 Raincloud plot showing that the best alphabet orders found at the conclusion of local search (orange) give noticeably better compression than that achieved using either randomly sampled alphabet orders (green) or the ASCII alphabet order (horizontal line). The compression achieved by random samples of alphabet orderings are displayed in green. The best achieved via local search with SWAP only is shown in orange, (also see Section. 5.4). The change in compression for the different local search initialization orderings at the start of the search are shown in blue, and these overlap with the random samples. The compression when using the ASCII alphabet is plotted as a horizontal blue line and can be seen at the lower end of the random samples.

13 14 start of the search, nor is there consistently an initialization order that would 15 produce a good local minimum across all files. The range of random sample 16 fitness may completely cover the fixed start positions as in alice29.txt or 17 lay above many of the best fitness starts as in fields.c. Overall the range of 18 random sample starts covers a large amount of solutions that are found using 19 the fixed start positions in our tested files. 20 The steep improvement early in the search suggests that a limited search

The steep improvement early in the search suggests that a limited search may still be beneficial. If the search is terminated early, ASCII and Chapin Tate are the best orderings from which to start the search (Fig. 5).

While using a random initialization still yields an improvement in fitness over time, the overall change in fitness is not as good as choosing a fixed initialization for the explored texts. It may be possible for multiple orderings to achieve around the same fitness for 1000 neighbor evaluations.

to achieve around the same intress for 1000 heighbor evaluations.
From this we conclude that the landscape has lots of local optima and
that the path through the landscape is therefore important. We examine other
methods such as reverse and random neighbor orderings, and using INSERT to
make further jumps in the landscape.

5.6 Local Search Operators: Swap and Insert

The path that the local search explores through the search space is important in determining where in the space the local optima is found. Evaluating more local search neighbors may therefore lead to finding better neighbors and a better overall optima. Since SWAP moves two elements into new locations at once. We therefore consider the INSERT operator, either in combination with SWAP (as first or second operator) or alone.

41 Tab. 5 shows the number of steps taken using each of the different search 42 operators to find an ordering that performs better than the best of the 240,000 43 randomly sampled orderings. We note that local search only requires a few 44 steps before outperforming random sampling, independently of any search 45 operators, and typically takes only a few seconds to compute. Indeed, table 6 46 shows that methods based on local search create a large number of updates 47 when compared to a naive random sampling of the search space. While the 48 average number of updates obtained with the latter is close to the theoretical 49 one (12.4 vs. 12.38), we see that local search algorithms provide substantially 50 more updates. For instance, the SWAP method using the lexicographic order 51 generates on average 236 updates across 10 files. Such a number of updates 52 with random sampling would on expectation require more than 10^{100} samples 53 $(\approx e^{236.5})$, which is today not computable. 54

Methods involving randomized neighbor orderings perform well in the time
taken to beat the best of the 240,000 random samples compared to all other
methods. Of these, the SWAP THEN INSERT operator performs best.

However, to fully locate any local minimum may in some cases take a very long time (Fig. 6). Our experiments are limited to 10 million steps for any single run, which is reached for some configurations. When considering the initialization that locates the best fitness for any method, we find an 62

Heuristics for the RLBWT Alphabet Ordering Problem

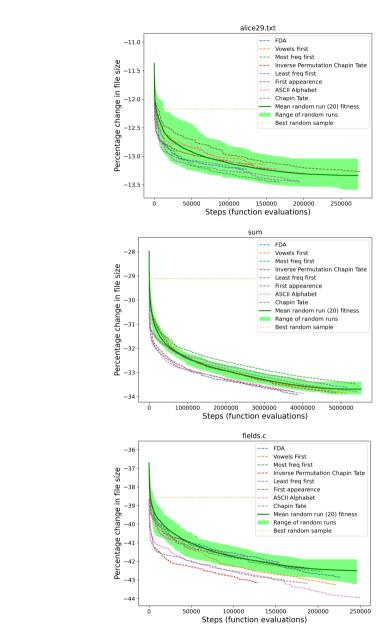

Figure 4 Local search using SWAP, LEX from different alphabet order initialization methods over time until a local minimum is reached. It can be observed that there is no best initial order that consistently results in the best local minima for all texts.

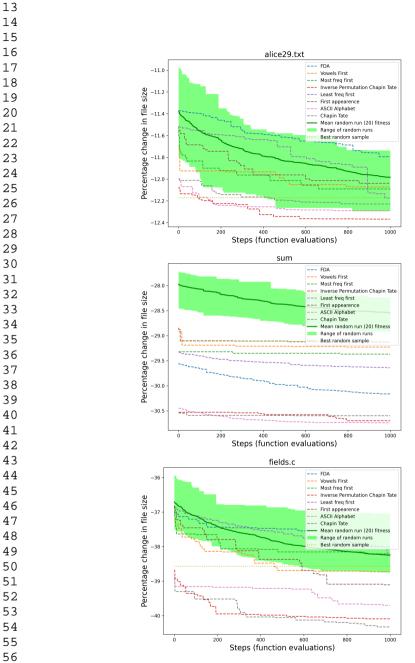

Figure 5 Local search for different alphabet order initialization methods over time with SWAP, LEX, limited to 1000 neighbor evaluations. It can be observed that there is no best initial order that consistently results in the best local minima for all texts, and that the best initialization order is dependent on the number of steps performed.

Springer Nature 2021 LATEX template

22 Heuristics for the RLBWT Alphabet Ordering Problem

Table 5 The minimum number of local search steps for the best initialization to find an ordering performing better than the best ordering out of the 240,000 randomly sampled orderings. Files asyoulik.txt, cp.html, fields.c, ptt5, lcet10.txt, and sum are not shown because no local search steps were needed, as one of the initial orderings was already better than the randomly sampled orderings without the need for search. I=INSERT, S=SWAP, ItS=INSERT then SWAP, StI=SWAP then INSERT.

Method	alice29.txt	grammar.lsp	plrabn12.txt	xargs.1	All Others

StI, RevLex	105	421	235	428	0

Table 6 Number of successive improvements obtained with two local search algorithms compared to random sampling for ASCII ordering. Total number of steps are within brackets. Random sampling has created on average 12.4 updates across the 10 files while the theoretical mean number of updates for random sampling is approximately 12.38 for 240K samples (See section 4.1). In contrast, local search algorithms deliver significantly more updates to the compression when compared to random sampling.

File	Random Sampling	Swap, Lex	Insert, Lex
alice29.txt	14 (240K)	231 (205.84K)	319 (519.2 K)
asyoulik.txt	11 (240K)	218 (125.32K)	310 (399.06K)
cp.html	17 (240 K)	176 (242.68 K)	241 (491.92 K)
fields.c	10 (240K)	157 (249.31 K)	169 (496.97 K)
grammar.lsp	11 (240K)	67 (65.54 K)	$86 (161.88 \mathrm{K})$
lcet10.txt	11 (240 K)	259 (340.97 K)	380 (934.5 K)
plrabn12.txt	15 (240 K)	$383 (435.92 \mathrm{K})$	457 (929.79K)
ptt5	12 (240 K)	352 (1.25M)	549 (3.59M)
sum	10(240 K)	452 (4.03M)	561 (10M)
xargs.1	13 (240 K)	70~(63.98 K)	102 (192.87 K)
average number of updates	12.4	236.5	317.4

49 initial steep drop in fitness for all methods, and that there are groupings of 50 methods that perform similarly. Generally the methods involving randomized 51 neighbor orderings perform well in few steps and have a fitness which remains 52 competitive with the LEX and REVLEX methods. We observe that even when 53 the number of steps is limited to relatively few in comparison to the number 54 needed to reach a local minimum, the percentage change in file size reached 55 may still be good.

This is further demonstrated when considering the final fitness achieved in all runs across all methods. Across our tested files, the number of required steps to locate a minimum splits the methods into three groups (in increasing order of steps): random neighbor ordering methods, SWAP and SWAP-first methods, and INSERT and INSERT-first methods (Fig. 7). Even when considering the final

fitness achieved, a randomized neighbor ordering remains competitive (Fig. 8).
The file sum is not shown as it has data which was not run to completion due
to prohibitive runtimes (Section. 5.1). However, the trend described also holds
with the completed data for sum.
When completing the search to a local minimum INSERT and INSERT-first.

When completing the search to a local minimum, INSERT and INSERT-first methods perform slightly better than methods involving SWAP, however the INSERT and INSERT-first methods may take prohibitively long compared to SWAP, as they search a wider neighborhood, for very little gain.

6 Conclusion and Future Work

The BWT is an important string transformation, enabling a concise, searchable representation of a string. It relies on ordering the characters in the string and this is usually assumed to be ASCII ordering, without exploring whether alternatives might be more effective.

30 We studied heuristics for the computationally hard RLBWT Alphabet 31 Ordering Problem which takes a string s of length n over an alphabet Σ 32 of size σ and seeks an ordering of Σ for $RLE(BWT(s, \Sigma))$ that minimizes 33 $|RLE(BWT(s,\Sigma))|$. We have performed extensive benchmarking using files 34 from the Canterbury corpus and implemented the experimentation on Super 35 Computing Wales HPC. We started by inspecting a large sample space of 36 240,000 randomly sampled alphabet orderings and found only limited improve-37 ment over the ASCII ordering. This motivated searching local neighborhoods 38 to improve fitness - this was achieved using a First-Improvement algorithm.

39 Various initializations have been applied to the test files to attempt to 40 speed up the search which include: ASCII order, letter frequency and order 41 of appearance, and a hand-tuned ordering given by Chapin and Tate (1998). 42 Jumping around the complex landscape was implemented with neighborhood 43 search using SWAP and INSERT operators as well as combinations of these 44 operators. Additionally varying the neighbors of an alphabet ordering has 45 been explored, searching them lexicographically, reverse-lexicographically, and 46 randomly. Overall, we inspected a combination of 9 initializations, 4 oper-47 ators, and 3 neighborhood search methods, giving a total of 108 algorithm 48 49 configurations.

The number of search steps needed to outperform the best result of random sampling was found to be relatively few and could be computed in seconds, but quickly increased for achieving a local minimum. Indeed, we demonstrated that reaching a similar number of improvements with random sampling would require investigating a much larger number of random samples (e.g., $> 10^{100}$), which is not feasible to compute.

The chosen initial alphabet order was found to influence the best solution that can be found, and we demonstrated this using the SWAP operator. While we observed variation in the initial ordering which achieved the best fitness within a time limit, there is not necessarily one best initial ordering. However,

24 Heuristics for the RLBWT Alphabet Ordering Problem

all initializations exhibit a clear decrease in file size followed by a large number of steps until the local minimum is reached.

16 We observed that the random neighbor ordering methods perform well 17 in the early stages of the search, and while not the best they remain com-18 petitive overall. INSERT and INSERT-first methods are slower than SWAP and 19 SWAP-first methods to reach a local minimum but will usually achieve a bet-20 ter compression. Although our empirical evidence shows that local search is 21 indeed effective for improving the RLBWT, and trade-offs occur, nonetheless 22 we are still able to recommend a time-limited local search using SWAP with 23 Random neighborhood exploration to improve rapidly upon the ASCII order-24 ing. If more computational time is available to explore a better ordering then 25 we recommend a local search using INSERT THEN SWAP with Lexicographic 26 neighborhood exploration. 27

We found it surprising that the ASCII ordering performs very well when compared to a random order. Also, it works relatively well as an initialization for the local search. If limited time is available we recommend the Chapin Tate ordering to start the search, or a random order to initialize a longer search. However, there is no clear best initialization suiting different files considered in the corpus.

This is a difficult problem in theory and we have now demonstrated that this is a challenging problem in practice for the range of files in the Canterbury Corpus, with no clear winning strategy. We have demonstrated that navigating trade-offs can be worthwhile for enhancing compressibility. Our local search performs much better (faster convergence, better fitness) than random sampling and is useful even when computational time is limited.

In future work we intend to investigate further what constitutes a good alphabet ordering, the effect that different changes to an ordering can have on the transformed string, what factors contribute to the quality of an ordering for a given string and why some orderings perform better than others, in relation to the type of data (for instance natural language versus other structured data).

We want to determine which characters can be moved to benefit the search and to use this knowledge to inspire new and more specific local search operators. This may include using operators which re-order multiple characters at a time or incorporation of various crossover operators. In addition different encoding methods for RLE may give better results and should be investigated.
